**Abstract.** The main goal of this article is to put some known results in a common perspective and to simplify their proofs.

We start with a simple proof of a result from Vereshchagin [10] saying that  $\limsup_n C(x|n)$  (here  $C(x|n)$  is conditional (plain) Kolmogorov complexity of  $x$  when  $n$  is known) equals  $C^{\mathbf{0}'}(x)$ , the plain Kolmogorov complexity with  $\mathbf{0}'$ -oracle.

Then we use the same argument to prove similar results for prefix complexity, a priori probability on binary tree and measure of effectively open sets, and also to improve results of Muchnik [5] about limit frequencies.

As a by-product, we get a criterion of  $\mathbf{0}'$  Martin-Löf randomness (called also 2-randomness) proved in Miller [4]: a sequence  $\omega$  is 2-random if and only if there exists  $c$  such that any prefix  $x$  of  $\omega$  is a prefix of some string  $y$  such that  $C(y) \geq |y| - c$ . (In the 1960ies this property was suggested in Kolmogorov [2] as one of possible randomness definitions; its equivalence to 2-randomness was shown in Miller [4]). Miller [4] and Nies et al. [6] proved another 2-randomness criterion:  $\omega$  is 2-random if and only if  $C(x) \geq |x| - c$  for some  $c$  and infinitely many prefixes  $x$  of  $\omega$ .

We show that the low-basis theorem can be used to get alternative proofs of our results on Kolmogorov complexity and to improve the result about effectively open sets. This stronger version implies the 2-randomness criterion mentioned in the previous sentence.

## 1 Plain complexity

We denote by  $\{0, 1\}^*$  the set of binary strings and by  $\{0, 1\}^\infty$  the set of infinite binary sequences. For  $x \in \{0, 1\}^*$ , we denote by  $C(x)$  the plain complexity of  $x$  (the length of the shortest description of  $x$  when an optimal description method is fixed, see Li and Vitanyi [3]; no requirements about prefixes). By  $C(x|n)$  we mean conditional complexity of  $x$  when  $n$  is given, see for example Li and Vitanyi [3]. Superscript  $\mathbf{0}'$  in  $C^{\mathbf{0}'}$  means that we consider the relativized version of complexity to the oracle  $\mathbf{0}'$ , the universal computably enumerable set.

The following result was proved in Vereshchagin [10]. We provide a simple proof for it.

**Theorem 1.** For all  $x \in \{0, 1\}^*$ :

$$\limsup_{n \rightarrow \infty} C(x|n) = C^{\mathbf{0}'}(x) + O(1).$$

(in this theorem and below, an equality of type “ $f(x) = g(x) + O(1)$ ” means that there is a constant  $c$  such that for all  $x$ ,  $|f(x) - g(x)| < c$ )

*Proof.* We start in the easy direction. Let  $\mathbf{0}_n$  be the (finite) set consisting of the elements of the universal enumerable set  $\mathbf{0}'$  that have been enumerated after  $n$  steps of computation (note that  $\mathbf{0}_n$  can be computed from  $n$ ). If  $C^{\mathbf{0}'}(x) \leq k$ , then there exists a description (program) of size at most  $k$  that generates  $x$  using  $\mathbf{0}'$  as an oracle. Only finite part of the oracle can be used, so  $\mathbf{0}'$  can be replaced by  $\mathbf{0}_n$  for all sufficiently large  $n$ , and oracle  $\mathbf{0}_n$  can be reconstructed if  $n$  is given as a condition. Therefore,  $C(x|n) \leq k + O(1)$  for all sufficiently large  $n$ , and

$$\limsup_{n \rightarrow \infty} C(x|n) \leq C^{\mathbf{0}'}(x) + O(1).$$

For the reverse inequality, fix  $k$  and assume that  $\limsup C(x|n) < k$ . This means that for all sufficiently large  $n$  the string  $x$  belongs to the set

$$U_n = \{u \mid C(u|n) < k\}.$$

The family  $U_n$  is an enumerable family of sets (given  $n$  and  $k$ , we can generate  $U_n$ ); each of these sets has at most  $2^k$  elements. We need to construct a  $\mathbf{0}'$ -computable process that given  $k$  generates at most  $2^k$  elements, and among them all elements that belong to  $U_n$  for all sufficiently large  $n$ . (Then strings of length  $k$  may be assigned as  $\mathbf{0}'$ -computable codes of all generated elements.)

To describe this process, consider the following operation: for some  $u$  and  $N$  add  $u$  to all  $U_n$  such that  $n \geq N$ . (In other terms, we add a horizontal ray starting from  $(N, u)$  to the set  $\mathcal{U} = \{(n, u) \mid u \in U_n\}$ .) This operation is *acceptable* if all  $U_n$  still have at most  $2^k$  elements after it (i.e., if before this operation all  $U_n$  such that  $n \geq N$  either contain  $u$  or have less than  $2^k$  elements).

For any given triple  $u, N, k$ , we can find out using  $\mathbf{0}'$ -oracle whether this operation is acceptable or not. Indeed, the operation is not acceptable if and only if some  $U_n$  for  $n \geq N$  contains at least  $2^k$  elements that are distinct from  $u$ . Formally, the operation is not acceptable if

$$(\exists n \geq N) |U_n \setminus \{u\}| \geq 2^k,$$

and this is an enumerable condition as the  $U_n$  are themselves enumerable. Now for all pairs  $(N, u)$  (in some computable order) we perform the  $(N, u)$ -operation if it is acceptable. (The elements added to some  $U_i$  remain there and are taken into account when next operations are attempted.) This process is  $\mathbf{0}'$ -computable since after any finite number of operations the set  $\mathcal{U}$  is enumerable (without any oracle) and its enumeration algorithm can be  $\mathbf{0}'$ -effectively found (uniformly in  $k$ ).

Therefore the set of all elements  $u$  that participate in acceptable operations during this process is uniformly  $\mathbf{O}'$ -enumerable. This set contains at most  $2^k$  elements (otherwise  $U_n$  would become too big for large  $n$ ). Finally, this set contains all  $u$  such that  $u$  belongs to the (original)  $U_n$  for all sufficiently large  $n$ . Indeed, the operation is always acceptable if the element we want to add is already present!

The proof has the following structure. We have an enumerable family of sets  $U_n$  that all have at most  $2^k$  elements. This implies that the set

$$U_\infty = \liminf_{n \rightarrow \infty} U_n$$

has at most  $2^k$  elements where, as usual, the  $\liminf$  of a sequence of sets is the set of elements that belong to almost all sets of the sequence. If  $U_\infty$  were  $\mathbf{O}'$ -enumerable, we would be done. However, this may be not the case: the criterion

$$u \in U_\infty \Leftrightarrow \exists N (\forall n \geq N) [u \in U_n]$$

has  $\exists\forall$  prefix before an enumerable (not necessarily decidable) relation, that is, one quantifier more than we want (to guarantee that  $U_\infty$  is  $\mathbf{O}'$ -enumerable). However, in our proof we managed to cover  $U_\infty$  by a set that is  $\mathbf{O}'$ -enumerable and still has at most  $2^k$  elements.

## 2 Prefix complexity and a priori probability

We now prove a similar result for prefix complexity (or, in other terms, for a priori probability). Let us recall the definition. The function  $a(x)$  on binary strings (or integers) with non-negative real values is called a *semimeasure* if  $\sum_x a(x) \leq 1$ . The function  $a$  is *lower semicomputable* if there exists a computable total function  $(x, n) \mapsto a(x, n)$  with rational values such that for every  $x$  the sequence  $a(x, 0), a(x, 1), \dots$  is a nondecreasing sequence that has limit  $a(x)$ .

There exists a maximal (up to a constant factor) lower semicomputable semimeasure  $m$  (see Zvonkin and Levin [11]). The value  $m(x)$  is sometimes called the *a priori probability* of  $x$ . In the same way we can define *conditional* a priori probability  $m(x|n)$  and  $\mathbf{O}'$ -relativized a priori probability  $m^{\mathbf{O}'}(x)$  (which is a maximal semimeasure among the  $\mathbf{O}'$ -lower semicomputable ones).

**Theorem 2.** *For all  $x \in \{0, 1\}^*$ :*

$$\liminf_{n \rightarrow \infty} m(x|n) = m^{\mathbf{O}'}(x)$$

*up to a  $\Theta(1)$  multiplicative factor (in other terms, two inequalities with  $O(1)$  factors hold).*

*Proof.* If  $m^{\mathbf{O}'}(x)$  is greater than some  $\varepsilon$ , then for sufficiently large  $n$  the value  $m^{\mathbf{O}^n}(x)$  is also greater than  $\varepsilon$ . (Indeed, this inequality is established at some

finite stage when only a finite part of  $\mathbf{O}'$  is used.) We may assume without loss of generality that the function  $x \mapsto m^A(x)$  is a semimeasure for any  $A$  (recalling the construction of the maximal semimeasure). Then, similarly to the previous theorem, we have

$$\liminf_{n \rightarrow \infty} m(x|n) \geq \liminf_{n \rightarrow \infty} m^{\mathbf{O}^n}(x) \geq m^{\mathbf{O}'}(x)$$

up to constant multiplicative factors. Indeed, for the first inequality, notice that we can define a conditional lower semicomputable semimeasure  $\mu$  by  $\mu(x|n) = m^{\mathbf{O}^n}(x)$ . By maximality of  $m$ , we have  $\mu(x|n) \leq m(x|n)$  for all  $x, n$ , up to a multiplicative factor. For the second inequality, recall that  $m^{\mathbf{O}'}(x)$  is the nondecreasing limit of an  $\mathbf{O}'$ -computable sequence  $m^{\mathbf{O}'}(x, 0), m^{\mathbf{O}'}(x, 1), \dots$ . Let  $s$  be such that  $m^{\mathbf{O}'}(x, s) \geq \frac{1}{2}m^{\mathbf{O}'}(x)$ . Since the computation of  $m^{\mathbf{O}'}(x, s)$  only uses finitely many bits of  $\mathbf{O}'$ , we have for all large enough  $n$ :  $m^{\mathbf{O}^n}(x, s) = m^{\mathbf{O}'}(x, s) \geq \frac{1}{2}m^{\mathbf{O}'}(x)$  and thus  $m^{\mathbf{O}^n}(x) \geq \frac{1}{2}m^{\mathbf{O}'}(x)$ .

The other direction of the proof is also similar to the second part of the proof of Theorem 1. Instead of enumerable finite sets  $U_n$  we now have a sequence of (uniformly) lower semicomputable functions  $x \mapsto m_n(x) = m(x|n)$ . Each of the  $m_n$  is a semimeasure. We need to construct an  $\mathbf{O}'$ -lower semicomputable semimeasure  $m'$  such that

$$m'(x) \geq \liminf_{n \rightarrow \infty} m_n(x)$$

Again, the  $\liminf$  itself cannot be used as  $m'$ : we do have  $\sum_x \liminf_n m_n(x) \leq 1$  as  $\sum_x m_n(x) \leq 1$  for all  $n$ , but unfortunately the equivalence

$$r < \liminf_{n \rightarrow \infty} m_n(x) \Leftrightarrow (\exists r' > r)(\exists N)(\forall n \geq N)[r' < m_n(x)]$$

has too many quantifier alternations (one more than needed; note that the quantity  $m_n(x)$  is lower semicomputable making the [...] condition enumerable). The similar trick helps. For a triple  $(r, N, u)$  consider an *increase operation* that increases all values  $m_n(u)$  such that  $n \geq N$  up to a given rational number  $r$  (not changing them if they were greater than or equal to  $r$ ). This operation is *acceptable* if all  $m_n$  remain semimeasures after the increase.

The question whether the increase operation is acceptable is  $\mathbf{O}'$ -decidable. And if it is acceptable, by performing it we get a new (uniformly) lower semicomputable sequence of semimeasures. We can then try to perform an increase operation for some other triple. Doing that for all triples (in some computable ordering), we can then define  $m'(u)$  as the upper bound of  $r$  for all successful  $(r, N, u)$  increase operations (for all  $N$ ). This gives a  $\mathbf{O}'$ -lower semicomputable function; it is a semimeasure since we verify the semimeasure inequality for every successful increase attempt; finally,  $m'(u) \geq \liminf m_n(u)$  since if  $m_n(u) \geq r$  for all  $n \geq N$ , then the  $(r, N, u)$ -increase does not change anything and is guaranteed to be acceptable at any step.

The expression  $-\log m(x)$ , where  $m$  is the maximal lower semicomputable semimeasure, equals the so-called *prefix complexity*  $K(x)$  (up to an additive  $O(1)$  term; see for example Li and Vitanyi [3]). The same is true for relativized and conditional versions, and we get the following reformulation of the last theorem:

**Theorem 3.**

$$\limsup_{n \rightarrow \infty} K(x|n) = K^{\mathbf{0}'}(x) + O(1).$$

Another corollary improves a result of Muchnik [5]. For any (partial) function  $f$  from  $\mathbb{N}$  to  $\mathbb{N}$  let us define the *limit frequency*  $q_f(x)$  of an integer  $x$  as

$$q_f(x) = \liminf_{n \rightarrow \infty} \frac{\#\{i < n \mid f(i) = x\}}{n}$$

In other words, we look at the fraction of terms equal to  $x$  among the first  $n$  values  $f(0), \dots, f(n-1)$  of  $f$  (undefined values are also listed) and take the  $\liminf$  of these fractions. It is easy to see that for a total computable  $f$  the function  $q_f$  is a lower  $\mathbf{0}'$ -semicomputable semimeasure. Moreover, it is shown in Muchnik [5] that any  $\mathbf{0}'$ -semicomputable semimeasure  $\mu$  can be represented as  $\mu = q_f$  for some computable function  $f$ . In particular this implies that there exists a total computable function  $f$  such that  $q_f = \mathbf{0}'$  ( $\mathbf{0}'$  is defined on page 3).

We would like to extend Muchnik's result to partial computable functions  $f$ . The problem is that if  $f$  is only partial computable, the function  $q_f$  is no longer guaranteed to be lowersemicomputable. Using the second part of the proof of Theorem 2, we can nonetheless prove:

**Theorem 4.** *For any partial computable function  $f$ , the function  $q_f$  is upper bounded by a lower  $\mathbf{0}'$ -semicomputable semimeasure.*

Indeed, given a partial computable function  $f$ , for all  $n$ , we can define a semimeasure  $\mu_n$  by

$$\mu_n(x) = \frac{\#\{i < n \mid f(i) = x\}}{n}$$

which is lower semicomputable uniformly in  $n$ . On the one hand we have  $q_f = \liminf \mu_n$  and on the other hand we know from the proof of Theorem 2 that the  $\liminf$  of a sequence of (uniformly) lower semicomputable semimeasures is bounded by a  $\mathbf{0}'$ -lower semicomputable semimeasure. The result follows.

The same type of argument also is applicable to the so-called *a priori complexity* defined as negative logarithm of a maximal lower semicomputable semimeasure on the binary tree (see Zvonkin and Levin [11]). This complexity is sometimes denoted as  $KA(x)$  and we get the following statement:

**Theorem 5.**

$$\limsup_{n \rightarrow \infty} KA(x|n) = KA^{\mathbf{0}'}(x) + O(1).$$

(To prove this we define an increase operation in such a way that, on a given lower semicomputable semimeasure on the binary tree  $a$ , it increases not only  $a(x)$  but also  $a(y)$  for  $y$  that are prefixes of  $x$ , if necessary. The increase is acceptable if  $a(A)$  still does not exceed 1.)

It would be interesting to find out whether similar results are true for monotone complexity or not (the authors do not know this).

### 3 Open sets of small measure

In Section 1 we covered the  $\liminf$  of a sequence of finite uniformly enumerable sets  $U_i$  by a  $\mathbf{0}'$ -enumerable set  $V$  that is essentially no bigger than the  $U_i$  in a uniform way, i.e.,  $V$  can be effectively constructed given the enumerations of the  $U_i$  and an upper bound for their cardinalities. We now look at the continuous version of this problem where the  $U_i$  are open sets of small measure.

We will consider open sets in the Cantor space  $\{0, 1\}^\infty$  (the set of all infinite sequence of zeros and ones). An *interval*  $[x]$  (for a binary string  $x$ ) is formed by all sequences that have prefix  $x$ . Open sets are unions of intervals. An *effectively open* subset of  $\{0, 1\}^\infty$  is an enumerable union of intervals, i.e., the union of intervals  $[x]$  where strings  $x$  are taken from some enumerable set.

We consider standard (uniform Bernoulli) measure on  $\{0, 1\}^\infty$ : the interval  $[x]$  has measure  $2^{-l}$  where  $l$  is the length of  $x$ .

A classical theorem of measure theory says: *if  $U_0, U_1, U_2, \dots$  are open sets of measure at most  $\varepsilon$ , then  $\liminf_n U_n$  has measure at most  $\varepsilon$* , and this implies that *for every  $\varepsilon' > \varepsilon$  there exists an open set of measure at most  $\varepsilon'$  that covers  $\liminf_n U_n$* . Indeed,

$$\liminf_{n \rightarrow \infty} U_n = \bigcup_N \bigcap_{n \geq N} U_n,$$

and the measure of the union of an increasing sequence

$$V_N = \bigcap_{n \geq N} U_n,$$

equals the limit of measures of  $V_N$ , and all these measures do not exceed  $\varepsilon$  since  $V_N \subset U_N$ . It remains to note that for any measurable subset  $X$  of  $\{0, 1\}^\infty$  its measure  $\mu(X)$  is the infimum of the measures of open sets that cover  $X$ .

We now can try to “effectivize” this statement in the same way as we did before. In Section 1 we started with an (evident) statement: *if  $U_n$  are finite sets of at most  $2^k$  elements, then  $\liminf_n U_n$  has at most  $2^k$  elements* and proved its effective (in the halting problem) version: *for a uniformly enumerable family of open sets  $U_n$  that have at most  $2^k$  elements, the set  $\liminf_n U_n$  is contained in a uniformly  $\mathbf{0}'$ -enumerable set that has at most  $2^k$  elements*.

In Section 2 we did a similar thing with semimeasures. Again, the non-effective version is trivial: it says that if  $\sum_x m_n(x) \leq 1$  for every  $n$ , then  $\sum_x \liminf_n m_n(x) \leq 1$ . We have proved the effective version that provides a  $\mathbf{0}'$ -semicomputable upper bound for  $\liminf m_n$  that is a semimeasure.

For the statement about  $\liminf$  of open sets the effective version could look like this. Let  $\varepsilon > 0$  be a rational number and let  $U_0, U_1, \dots$  be an enumerable family of effectively open sets of measure at most  $\varepsilon$  each. Then for every rational  $\varepsilon' > \varepsilon$  there exists a  $\mathbf{0}'$ -effectively open set  $V$  of measure at most  $\varepsilon'$  that contains  $\liminf_{n \rightarrow \infty} U_n = \bigcup_N \bigcap_{n \geq N} U_n$ .

We will see in Section 8 that this is not true in general. However, some weaker statements are still true. They can be obtained by putting some extra requirements on the sets  $U_n$ , or by weakening the conclusion. Let us start with the simple case where the  $U_n$  form a computable family of clopen (closed and open) sets. Such a set is a finite union of intervals, and we assume that the list of these intervals can be computed given  $n$ .

**Theorem 6.** *Let  $U_n$  be a uniformly computable family of clopen sets. Suppose also that for all  $n$  the set  $U_n$  has measure at most  $\varepsilon$  for some rational  $\varepsilon$ . Then for every rational  $\varepsilon' > \varepsilon$  there exists a  $\mathbf{0}'$ -effectively open set  $V$  of measure at most  $\varepsilon'$  such that*

$$U_\infty = \liminf_{n \rightarrow +\infty} U_n \subseteq V$$

*Proof.* By definition

$$U_\infty = \bigcup_N \bigcap_{n \geq N} U_n,$$

therefore  $U_\infty$  is a union of the pairwise disjoint sets

$$F_0 = \bigcap_i U_i, \quad F_1 = \bigcap_{i \geq 1} U_i \setminus U_0, \quad F_2 = \bigcap_{i \geq 2} U_i \setminus U_1, \dots$$

(in other terms, a given to find  $x \in U_\infty$  belongs to  $F_k$  if the last  $U_i$  to which  $x$  does not belong is  $U_{k-1}$ ). Each of  $F_k$  is an effectively closed set (recall that each  $U_i$  is a finite union of intervals hence is closed). Since the sets  $F_k$  are disjoint and

$$\liminf_{n \rightarrow +\infty} U_n = \bigcup_k F_k,$$

we conclude that

$$\mu(\liminf_{n \rightarrow +\infty} U_n) = \sum_k \mu(F_k).$$

For each  $k$  the value  $\mu(F_k)$  is the limit over  $r$  of the (non-increasing) quantity  $\mu(\bigcap_{i=k}^r U_i \setminus U_{k-1})$  which is computable uniformly in  $(i, r)$ . Thus, with oracle  $\mathbf{0}'$ , one can compute  $\mu(F_k)$  for every  $k$  (with arbitrary precision) and find a stage  $r_k$  such that

$$\mu\left(\bigcap_{i=k}^{r_k} U_i \setminus U_{k-1}\right) < \mu(F_k) + (\varepsilon' - \varepsilon)/2^{k+1}$$

Set  $F'_k = \bigcap_{i=k}^{r_k} U_i \setminus U_{k-1}$ . Notice that  $F'_k$  contains  $F_k$ , and is itself an clopen set, and the list of corresponding intervals can be  $\mathbf{0}'$ -effectively computed given  $k$ . Thus,

$$V = \bigcup_k F'_k$$

is a  $\mathbf{0}'$ -effectively open set, contains  $\bigcup_k F_k = U_\infty$  and has measure at most

$$\underbrace{\sum_k \mu(F_k)}_{=\mu(U_\infty) \leq \varepsilon} + \underbrace{\sum_k (\varepsilon' - \varepsilon)/2^{k+1}}_{=\varepsilon' - \varepsilon},$$

i.e. at most  $\varepsilon'$ . Hence,  $V$  satisfies all the requirements.

As we have said, instead of putting additional requirements on the sequence  $U_i$  (requiring it to be a computable sequence of clopen sets) we can weaken the conclusion. The techniques presented in the previous sections allow us to prove the following:

**Theorem 7.** *Let  $\varepsilon > 0$  be a rational number and let  $U_n$  be a uniformly enumerable family of effectively open sets of measure at most  $\varepsilon$  each. Then there exists a  $\mathbf{0}'$ -effectively open set of measure at most  $\varepsilon$  that contains*

$$\bigcup_N \text{Int} \left( \bigcap_{n \geq N} U_n \right)$$

(and the construction is uniform given  $\varepsilon$  and an index for the sequence  $U_n$ )

Here  $\text{Int}(X)$  denotes the interior part of  $X$ , i.e., the largest open subset of  $X$ . In this case we do not need to consider  $\varepsilon' > \varepsilon$  (not a surprise, since the union of open sets is open).

*Proof.* Following the same scheme, for every string  $x$  and integer  $N$  we consider  $(x, N)$ -operation that adds  $[x]$  to all  $U_n$  such that  $n \geq N$ . This operation is *acceptable* if the measures of all the  $U_n$  remain at most  $\varepsilon$  for each  $n$ . This can be checked using  $\mathbf{0}'$  as an oracle (if the operation is not acceptable, it becomes known after a finite number of steps).

We attempt to perform this operation (if acceptable) for all pairs in some computable order. The union of all added intervals for all accepted pairs is  $\mathbf{0}'$ -effectively open. If some sequence belongs to the union of the interior parts, then it is covered by some interval  $[u]$  that is a subset of  $U_n$  for all sufficiently large  $n$ . Then some  $(u, N)$ -operation is acceptable since it actually does not change anything and therefore  $[u]$  is a part of an  $\mathbf{0}'$ -open set that we have constructed.

In Section 6 we will return to this topic and state in Theorem 10 one more result about the lim inf of small sets.

## 4 Kolmogorov and 2-randomness

Theorem 7 has an historically remarkable corollary. When Kolmogorov tried to define randomness in 1960ies, he started with the following approach. A string  $x$

of length  $n$  is “random” if its complexity  $C(x)$  (or conditional complexity  $C(x|n)$ ; in fact, these requirements are almost equivalent) is close to  $n$ : the *randomness deficiency*  $d(x)$  is defined by

$$d(x) = |x| - C(x)$$

(here  $|x|$  stands for the length of  $x$ ). This sounds reasonable, but if we then define a random sequence as a sequence whose prefixes have deficiencies bounded by a constant, such a sequence does not exist at all: Martin-Löf showed that every infinite sequence has prefixes of arbitrarily large deficiency, and suggested a different definition of randomness using effectively null sets. Later more refined versions of randomness deficiency (using monotone or prefix complexity) appeared that make the criterion of randomness in terms of deficiencies possible. But before that, in 1968, Kolmogorov wrote: “The most natural definition of infinite Bernoulli sequence is the following:  $x$  is considered  $m$ -Bernoulli type if  $m$  is such that all  $x^i$  are *initial segments* of the finite  $m$ -Bernoulli sequences. Martin-Löf gives another, possibly narrower definition”, see Kolmogorov [2], p. 663.

Here Kolmogorov speaks about “ $m$ -Bernoulli” finite sequence  $x$  (this means that  $C(x|n, k)$  is greater than  $\log \binom{n}{k} - m$  where  $n$  is the length of  $x$  and  $k$  is the number of ones in  $x$ ). For the case of uniform Bernoulli measure (where  $p = q = 1/2$ ) one would reformulate this definition as follows. Let us define

$$\bar{d}(x) = \inf\{d(y) \mid x \text{ is a prefix of } y\}$$

and require that  $\bar{d}(x)$  is bounded for all prefixes of an infinite sequence  $\omega$ . It is shown by Miller [4] that this definition is equivalent to Martin-Löf randomness relativized to  $\mathbf{0}'$  (called also *2-randomness*):

**Theorem 8.** *A sequence  $\omega$  is Martin-Löf  $\mathbf{0}'$ -random if and only if the quantities  $\bar{d}(x)$  for all prefixes  $x$  of  $\omega$  are bounded from above by a common constant.*

It turns out that the forward direction of the equivalence stated in Theorem 8 follows easily from Theorem 7.

*Proof.* Assume that  $\bar{d}$ -deficiencies for prefixes of  $\omega$  are not bounded. According to Martin-Löf definition, we have to construct for a given  $c$  an  $\mathbf{0}'$ -effectively open set that covers  $\omega$  and has measure at most  $2^{-c}$ .

Fix some  $c$ . For each  $n$  consider the set  $D_n^c$  of all sequences  $u$  of length  $n$  such that  $C(u) < n - c$  (i.e., sequences  $u$  of length  $n$  such that  $d(u) > c$ ). It has at most  $2^{n-c}$  elements. By definition of  $\bar{d}$ , the requirement  $\bar{d}(x) > c$  means that every string extension  $y$  of  $x$  belongs to  $D_m^c$  where  $m$  is the length of  $y$ . This implies that  $[x]$  (=set of sequences with prefix  $x$ ) is contained in every  $U_m$  for  $m \geq |x|$ , where

$$U_m^c = \bigcup_{u \in D_m^c} [u]$$

(in other words  $U_m^c$  is the set of all sequences that have prefixes in  $D_m^c$ ). Therefore, in this case the interval  $[x]$  is a subset of  $\bigcap_{m \geq |x|} U_m^c$  and (being open)

is a subset of its interior. To sum up, we have proven that if an infinite sequence  $\omega$  has a prefix  $x$  such that  $\bar{d}(x) > c$ , then

$$\omega \in \text{Int} \left( \bigcap_{m \geq |x|} U_m^c \right)$$

Now, note that each  $U_m^c$  is effectively open uniformly in  $m, c$  as  $D_m^c$  is enumerable uniformly in  $m, c$ . Moreover, there are at most  $2^{m-c}$  strings in  $D_m^c$ , hence the measure of  $U_m^c$  is at most  $2^{-c}$ . Applying Theorem 7, there exists a  $\mathbf{0}'$ -effectively open (uniformly in  $c$ ) set  $V_c$  such that  $V_c$  has measure at most  $2^{-c}$  and

$$\bigcup_N \text{Int} \left( \bigcap_{m \geq N} U_m^c \right) \subseteq V_c$$

Note that this tells us in particular that the sequence  $(V_c)_{c \in \mathbb{N}}$  forms an  $\mathbf{0}'$ -Martin-Löf test. Thus, if a sequence  $\omega$  is  $\mathbf{0}'$ -Martin-Löf random, it only belongs to finitely many  $V_c$ . Let then  $b$  be such that  $\omega \notin V_b$ . By the above argument, this means that  $\omega$  has no prefix  $x$  such that  $\bar{d}(x) > b$ , or equivalently that for every prefix  $x$  of  $\omega$ ,  $\bar{d}(x) \leq b$ . This proves the forward direction of the equivalence.

For the sake of completeness, we give the proof of the reverse implication in terms of Martin-Löf tests (Miller [4] provided a proof solely in terms of Kolmogorov complexity). Assume that a sequence  $\omega$  is covered (for each  $c$ ) by a  $\mathbf{0}'$ -computable sequence of intervals  $I_0, I_1, \dots$  of total measure at most  $2^{-c}$ . (We omit  $c$  in our notation, but all these constructions depend on  $c$ .)

Using the approximations  $\mathbf{0}_n$  of  $\mathbf{0}'$  by performing at most  $n$  steps of computation for each  $n$  we get another (now computable) family of intervals  $I_{0,n}, I_{1,n}, \dots$  such that  $I_{i,n} = I_i$  for every  $i$  and sufficiently large  $n$ . We may assume without loss of generality that  $I_{i,n}$  either has size at least  $2^{-n}$  (i.e., is determined by a string of length at most  $n$ ) or equals  $\perp$  (a special value that denotes the empty set) since only the limit behavior is prescribed. Moreover, we may also assume that  $I_{i,n} = \perp$  for  $i > n$  and that the total measure of all  $I_{0,n}, I_{1,n}, \dots$  does not exceed  $2^{-c}$  for every  $n$ , by deleting the excessive intervals in order (the stabilization guarantees that all limit intervals will be eventually let through).

Since  $I_{i,n}$  is defined by intervals of size at least  $2^{-n}$ , we get at most  $2^{n-c}$  strings of length  $n$  covered by intervals  $I_{i,n}$  for any given  $n$  and all  $i$ . This set is decidable (recall that only  $i$  not exceeding  $n$  are used), therefore each string in this set can be defined, assuming  $c$  is known, by a string of length  $n - c$ , binary representation of its ordinal number in this set. Note that this string also determines  $n$  if  $c$  is known.

Returning to the sequence  $\omega$ , we note that it is covered by some  $I_i$  and therefore is covered by  $I_{i,n}$  for this  $i$  and all sufficiently large  $n$  (after the value of  $I_{i,n}$  is stabilized), say, for all  $n \geq N$ . Let  $u$  be the prefix of  $\omega$  of length  $N$ . All continuations of  $u$  of any length  $n$  are covered by  $I_{i,n}$  and thus have

complexity less than  $n - c + O(1)$ , conditional to  $c$ , hence complexity less than  $n - c + 2 \log c + O(1)$ . This means that  $\bar{d}(u) \geq c - 2 \log c - O(1)$ .

Such a string  $u$  can be found for every  $c$ , therefore  $\omega$  has prefixes of arbitrarily large  $\bar{d}$ -deficiency.

In fact a stronger statement than Theorem 8 is proved in Miller [4] and Nies et al. [6]; our tools are still too weak to get this statement. However, the low basis theorem helps.

## 5 The low basis theorem

The low basis theorem is a classical result in recursion theory (see, e.g., Odifreddi [7]). It was used in Nies et al. [6] to prove 2-randomness criterion; analyzing this proof, we get theorems about limit complexities as byproducts. For the sake of completeness, we state the low-basis theorem and its simple proof.

**Theorem 9.** *Let  $U \subset \{0, 1\}^\infty$  be an effectively open set that does not coincide with  $\{0, 1\}^\infty$ . Then there exists a sequence  $\omega \notin U$  which is low, i.e.,  $\omega' =_{\mathbf{T}} \mathbf{0}'$*

Here  $\omega'$  is the jump of  $\omega$ ; the equation  $\omega' =_{\mathbf{T}} \mathbf{0}'$  means that the universal  $\omega$ -enumerable set is  $\mathbf{0}'$ -decidable.

Theorem 9 says that any effectively closed nonempty set contains a low element. For example, if  $P, Q \subset \mathbb{N}$  are enumerable inseparable sets, then the set of all separating sequences is an effectively closed set that does not contain computable sequences. We conclude, therefore, that there exists a non-computable low separating sequence.

*Proof.* Assume that an oracle machine  $M$  and an input  $x$  are fixed. The computation of  $M$  with oracle  $\omega$  on  $x$  may terminate or not depending on oracle  $\omega$ . Let us consider the set  $T(M, x)$  of all  $\omega$  such that  $M^\omega(x)$  terminates (for fixed machine  $M$  and input  $x$ ). This set is an effectively open set and if termination happens, it happens due to finitely many oracle values. This set together with  $U$  may cover the entire space  $\{0, 1\}^\infty$ ; this means that  $M^\omega(x)$  terminates for all  $\omega \notin U$ . If it is not the case, we can add  $T(M, x)$  to  $U$  and get a bigger effectively open set  $\hat{U}$  that still has nonempty complement such that  $M^\omega(x)$  does not terminate for all  $\omega \notin \hat{U}$ . Either way, this operation guarantees that the termination of the computation  $M^\omega(x)$  does not depend on the choice of  $\omega$  in the remaining nonempty effectively closed set (meaning that for all  $\omega_1, \omega_2$  in the remaining effectively closed set,  $M^{\omega_1}(x)$  terminates if and only if  $M^{\omega_2}(x)$  terminates).

This increase operation of the effectively open set can be performed for all pairs  $(M, x)$  sequentially. At each stage the open set  $U$  stays the same or is increased but in any case its complement remains nonempty. Hence, by compactness of  $\{0, 1\}^\infty$ , the open set  $U_\infty$  obtained in the limit will have nonempty complement. We claim that any sequence  $\omega \notin U_\infty$  is low. Indeed, by construction of  $U_\infty$ , for every  $M, x$ , the termination of the computation of  $M^\omega(x)$  is

independent on the choice of  $\omega$  in the complement of  $U_\infty$ .

Now, note that during the increase operation, if  $U \cup T(M, x)$  covers the entire space  $\{0, 1\}^\infty$ , this happens on some finite stage (by compactness), so  $\mathbf{O}'$  is enough to find out whether this happens or not, and on the next step we have again some effectively open (without any oracle) set. So the  $\mathbf{O}'$ -oracle is enough to say which of the computations  $M^\omega(x)$  terminate (as we have said, this does not depend on the choice of  $\omega$  in the remaining closed set). Therefore, for any  $\omega \notin U_\infty$  and any given pair  $M, x$ , the termination of the computation  $M^\omega(x)$  can be decided with oracle  $\mathbf{O}'$ . This precisely means that  $\omega' =_{\mathbf{T}} \mathbf{O}'$ , i.e. that  $\omega$  is low.

## 6 Using the low basis theorem

Let us show how Theorem 1 can be proved using the low basis theorem. As we have seen, we have an enumerable family of sets  $U_n$  each of which has at most  $2^k$  elements (say, strings) and need to construct effectively a  $\mathbf{O}'$ -enumerable set that has at most  $2^k$  elements and contains  $U_\infty = \liminf_n U_n$ .

In the special case where the sets  $U_n$  happen to be (uniformly) decidable,  $U_\infty$  is  $\mathbf{O}'$ -enumerable and we do not need any other set. The low basis theorem allows us to reduce the general case to this special one.

First, assume without loss of generality that for all  $n$ ,  $U_n$  contains only strings of length at most  $n$ . To see why we can do this, consider for all  $n$  the set  $\widehat{U}_n$  of strings in  $U_n$  that have length at most  $n$ . The sequence of  $\widehat{U}_n$  is uniformly enumerable: whenever an element  $x$  is enumerated into  $U_n$ , we enumerate it into  $\widehat{U}_n$  if and only if it has length at most  $n$ . Moreover, this does not change the  $\liminf$  (i.e.,  $\liminf U_n = \liminf \widehat{U}_n$ ), because any string  $x \in \liminf_n U_n$  belongs to almost all  $U_n$  hence will be allowed to enter any  $\widehat{U}_n$  for  $n \geq |x|$ , and thus will still belong to almost all  $\widehat{U}_n$ .

Having imposed this restriction on the  $U_n$ , let us consider the family of all “upper bounds” for  $U_n$ : by an upper bound we mean a sequence  $V_n$  of finite sets such that for all  $n$ , we have  $U_n \subseteq V_n$ ,  $\#V_n \leq 2^k$  and  $V_n$  contains strings of length at most  $n$ . The sequence  $V_0, V_1, \dots$  can be encoded as an infinite binary sequence: each  $V_i$  containing only strings of length at most  $n$  (there are  $2^{n+1} - 1$  of them), it can be encoded as a binary string of length  $2^{n+1} - 1$ . Then the sequence  $V_0, V_1, \dots$  can be simply encoded by concatenation of the individual encodings of the  $V_i$ .

For a binary sequence the property “to be an encoding of an upper bound for  $U_n$ ” is effectively closed (the restriction  $\#V_n < 2^k$  is decidable and the restriction  $U_n \subseteq V_n$  is co-enumerable). Therefore the low basis theorem can be applied. We get an upper bound  $V$  that is low. Then  $V_\infty = \liminf V_n$  is (uniformly in  $k$ )  $V'$ -enumerable (as we have said: with  $V$ -oracle the family  $V_n$  is uniformly decidable),

but since  $V$  is low, the  $V'$ -oracle can be replaced by the  $\mathbf{0}'$ -oracle, and we get the desired result.

This proof though being simple looks rather mysterious: we get something almost out of nothing! (As far as we know, this idea appeared in a slightly different context in Nies et al. [6].)

The same trick can be used to prove Theorem 2: here “upper bounds” are distributions  $M_n$  with rational values and finite support that are greater than  $m(x|n)$  but still are semimeasures. (Technical correction: first we have to assume that  $m(x|n) = 0$  if  $x$  is large, and then we have to weaken the restriction  $\sum M_n(x) \leq 1$  replacing 1 by, say, 2; this is needed since the values  $m(x|n)$  may be irrational).

Theorem 5 can be also proved in this way (upper bounds should be semimeasures on tree with rational values and finite support).

Returning to the topic of Section 3 we can use the low basis theorem allows to improve Theorem 6:

**Theorem 10.** *Let  $\varepsilon > 0$  be a rational number and let  $U_n$  be an uniformly enumerable family of effectively open sets. Assume that  $U_n$  has measure at most  $\varepsilon$  for every  $n$ . Assume also that  $U_i$  has “effectively bounded granularity”, i.e., all strings  $x$  that define the intervals in  $U_n$ , have length at most  $c(n)$  where  $c$  is a total computable function. Then for every  $\varepsilon' > \varepsilon$  there exists a  $\mathbf{0}'$ -effectively open set  $V$  of measure at most  $\varepsilon'$  that contains  $\liminf_{n \rightarrow \infty} U_n$  and this construction is uniform.*

*Proof.* We use the low basis theorem to reduce the general case to the case where the  $U_n$  form a computable family of finitely generated open sets.

Indeed, define an “upper bound” as a sequence  $W$  of sets  $W_n$  where  $W_n$  is a set of strings of length at most  $c(n)$  such that  $U_n$  is covered by the intervals generated by elements of  $W_n$ . Again  $W$  can be encoded as an infinite sequence of zeros and ones, and the property “to be an upper bound” is effectively closed. Applying the low basis theorem, we choose a low  $W$  and add it is an oracle; evidently,  $W_n$  is a  $W$ -computable family of finitely generated open sets. By Theorem 6, relativized to oracle  $W$ , for every  $\varepsilon' > \varepsilon$  there exists a  $W'$ -effectively open set  $V$  covering  $\liminf_n W_n$ , hence covering  $\liminf_n U_n$ . And since  $W'$  is Turing-equivalent to  $\mathbf{0}'$ , we are done.

## 7 Corollary on 2-randomness

Theorem 10 can be used to prove 2-randomness criterion from [4, 6]. In fact, this gives exactly the proof from [6]; the only thing we did is structuring the proof in two parts (formulating Theorem 10 explicitly and putting it in the context of other results on limits of complexities).

**Theorem 11** ([4, 6]). *A sequence  $\omega$  is  $\mathbf{0}'$  Martin-Löf random if and only if*

$$C(\omega_0\omega_1 \dots \omega_{n-1}) \geq n - c$$

*for some  $c$  and for infinitely many  $n$ .*

*Proof.* Let us first understand the relation between this theorem and Theorem 8. If

$$C(\omega_0\omega_1\dots\omega_{n-1}) \geq n - c$$

for infinitely many  $n$  and given  $c$ , then  $\bar{d}(x) \leq c$  for every prefix  $x$  of  $\omega$  (indeed, one can find the required continuation of  $x$  among prefixes of  $\omega$ ). As we know, this guarantees that  $\omega$  is  $\mathbf{O}'$  Martin-Löf random.

It remains to prove that if for all  $c$  we have

$$C(\omega_0\omega_1\dots\omega_{n-1}) < n - c$$

for all sufficiently large  $n$ , then  $\omega$  is not  $\mathbf{O}'$ -random. Using the same notation as in the proof of Theorem 8, we can say that  $\omega$  has a prefix in  $D_n$  and therefore belongs to  $U_n$  for all sufficiently large  $n$ . We can apply then Theorem 10 since  $U_n$  is defined using strings of length  $n$  (so  $c(n) = n$ ) and cover  $U_\infty$  (and therefore  $\omega$ ) by a  $\mathbf{O}'$ -effectively open set of small measure. Since this can be uniformly done for all  $c$ , the sequence  $\omega$  is not  $\mathbf{O}'$ -random.

## 8 The general case: $\Sigma_3^0$ sets and lim inf of open sets

In this section, we prove – as we have mentioned earlier – that it is not always possible to cover a lim inf of uniformly effectively open sets of small measures by a  $\mathbf{O}'$ -effectively open set of small measure. The first step towards this result is to prove that every  $\Sigma_3^0$  subset of  $\{0, 1\}^\infty$  can be written as the lim inf of a sequence of uniformly effectively open sets. The term  $\Sigma_3^0$  refers to the standard effective Borel hierarchy: effectively open sets are the  $\Sigma_1^0$  sets, effectively closed sets (i.e., the complements effectively open sets) are  $\Pi_1^0$  sets etc.: by induction, a  $\Sigma_n^0$  set is an effective countable union of  $\Pi_{n-1}^0$  sets and a  $\Pi_n^0$  set is an effective (countable) intersection of  $\Sigma_{n-1}^0$  sets. It is easy to see from the definition that a lim inf of a sequence of uniformly effectively open sets is a  $\Sigma_3^0$  set. Simpson [9] noted that the converse is also true:

**Theorem 12 (Simpson).** *For every  $\Sigma_3^0$  set  $S \subset \{0, 1\}^\infty$  there exists a sequence of uniformly effectively open sets  $V_n$  such that  $S = \liminf_{n \rightarrow +\infty} V_n$ .*

*Proof.* It is sufficient to construct a procedure which, given  $\omega \in \{0, 1\}^\infty$  as an oracle, enumerates a set  $X^\omega \subset \mathbb{N}$  such that  $\omega \in S \Leftrightarrow X^\omega$  is co-finite. Then we let  $V_n = \{\omega \mid n \in X^\omega\}$ .

Such a procedure is in fact provided by a proof of  $\Sigma_3^0$ -completeness of the cofiniteness property for enumerable sets (see, e.g., Rogers' textbook [8], Corollary XIV in Section 14.8). We give a sketch of this proof here.

As  $S$  is  $\Sigma_3^0$ , there exists a collection  $U_k^n$  of uniformly effectively open sets such that

$$S = \bigcup_n \bigcap_k U_k^n$$

For a given  $\omega$ , let

$$Z^\omega = \{(n, k) \mid \omega \in U_k^n\}$$

Then  $\omega$  is in  $S$  if and only if

$$\text{there exists an } n \text{ such that } (n, k) \in Z^\omega \text{ for all } k \quad (*)$$

We have to reduce this characterization to a characterization via cofiniteness of some  $\omega$ -enumerable set  $X^\omega$ , i.e., we have to transform (effectively and uniformly) the enumeration of  $Z^\omega$  into the enumeration of an  $X^\omega$  in such a way that

$$\omega \in S \Leftrightarrow \exists n \forall k [(n, k) \in Z^\omega] \Leftrightarrow X^\omega \text{ is cofinite}$$

To do so, we use a so-called “movable markers” construction. We first consider a countable series of counters: at each stage, the  $n$ th counter contains the maximal  $k$  such that all  $k$  pairs  $(n, 0), \dots, (n, k - 1)$  have already appeared in  $Z^\omega$ . The property  $(*)$  now means that some counter will increase indefinitely.

We also use “markers” that will locate the missing elements in  $X^\omega$ . Markers are numbered  $0, 1, 2, \dots$ . Initially the  $i$ th marker is located under the number  $i$ ; then markers can be moved to the right, but the  $i$ th marker is always on the left of  $(i + 1)$ th one (so all markers mark different numbers). When the  $n$ th counter increases, the number that was marked by the  $n$ th marker is added to  $X^\omega$ , and all the markers  $n, n + 1, n + 2, \dots$  are moved to the right (the  $i$ th marker moves to the previous place of the  $(i + 1)$ th one). The markers  $0, 1, \dots, n - 1$  do not move. Note the invariant relation: the currently enumerated part of  $X^\omega$  is the set of all non-marked numbers.

If the  $n$ th counter increases indefinitely, then the  $n$ th marker is moved infinitely many times, so  $X^\omega$  is cofinite (its complement consists of the final position of the markers  $0, 1, \dots, n - 1$ ). Conversely, if every counter increases only finitely many times, then each marker eventually reaches a final position, and these positions form an infinite complement of  $X^\omega$ .

From Theorem 12, we can prove the following theorem, due to Kjos-Hanssen [1]:

**Theorem 13 (Kjos-Hanssen).** *There exists a sequence  $U_n$  of uniformly effectively open sets such that:*

- $\mu(\liminf_n U_n) < 1/2$
- $\liminf_n U_n$  cannot be covered by any  $\mathbf{0}'$ -effectively open set of measure smaller than 1.

*Proof.* This can be obtained by relativizing standard results about Martin-Löf random sequences. The set of non-random sequences can be covered by an effectively open set of measure less than  $1/2$  (be definition). Therefore, the set of  $\mathbf{0}''$ -random sequence can be covered by an  $\mathbf{0}''$ -effectively open set, i.e., by  $\Sigma_3^0$ -set (as the standard results about the arithmetic hierarchy say, see, e.g., Rogers [8]).

On the other hand, for every effectively open set that has measure less than 1 there exists a  $\mathbf{0}'$ -computable sequence outside this set (indeed, the leftmost path of the binary tree representing its complement). And this can be relativized: for every  $\mathbf{0}'$ -effectively open set of measure less than 1 there is an  $\mathbf{0}''$ -computable sequence outside it.

Now, combining these two remarks and Theorem 12, we get the desired result. The  $\Sigma_3^0$  set mentioned above can be represented as  $\liminf$  of effectively open sets. If this set could be covered by an  $\mathbf{O}'$ -effectively open set of measure less than 1, we would be able to find a  $\mathbf{O}''$ -computable sequence outside it; this sequence is not  $\mathbf{O}''$ -random but is outside the set that has to cover all nonrandom (relative to  $\mathbf{O}''$ ) sequences.

Although a  $\liminf$  of a sequence of uniformly effectively open sets cannot in general be covered by an  $\mathbf{O}'$ -effectively open set of comparable measure, it is still possible that Theorem 10 can be improved. For example, the authors do not know whether the hypothesis of “effectively bounded granularity” of that theorem is actually necessary (or whether requiring  $U_n$  to be clopen is enough).

## 9 Fatou’s lemma

It would be nice to find some general result that could unite several cases that we have treated separately. Indeed, these results may be considered as constructive version of classical Fatou’s lemma.

This lemma guarantees that if  $\int f_n(x) d\mu(x) \leq \varepsilon$  for  $\mu$ -measurable functions  $f_0, f_1, f_2, \dots$ , then

$$\int \liminf_{n \rightarrow +\infty} f_n(x) d\mu(x) \leq \varepsilon.$$

The constructive version may require that  $f_i$  are lower semicomputable functions (probably with some additional conditions), and the statement could say that for every  $\varepsilon' > \varepsilon$  there exists a lower  $\mathbf{O}'$ -semicomputable function  $\varphi$  such that  $\liminf f_n(x) \leq \varphi(x)$  for every  $x$  and  $\int \varphi(x) d\mu(x) \leq \varepsilon'$ .

Special case of this lemma appears when  $f_i$  are indicator functions of some effectively open sets.

However, as we have seen in Section 8, some additional requirements are needed and we don’t know how to formulate them in a natural and general form. Instead of computably bounded granularity we may require that for each  $U_i$  we can provide a finite list of “simple” sets that have measure at most  $\varepsilon$  and guarantee that  $U_i$  is contained in one of them; a similar thing can be done for functions (a list of upperbounds of small measure). The source of difficulties here is the low basis theorem: it uses the compactness of Cantor space, so when choosing upper bound for the  $n$ th  $U_n$  or  $f_n$  we need to have in advance a finite list of possibilities.

Additional complications appear when the measure of the space where  $f_n$  are defined is infinite (and this is needed for the results of Section 1 and 2). Then we should artificially cut  $f_n$  in such a way that  $\liminf$  is not changed; this is possible in the special cases we need, but it is not clear how one can combine all these considerations into one (preferably not very boring) theorem.

Another open question: classical Fatou lemma usually is formulated in a stronger form:

$$\int \liminf_{n \rightarrow +\infty} f_n(x) d\mu(x) \leq \liminf_{n \rightarrow +\infty} \int f_n(x) d\mu(x)$$

there the right hand side has also  $\liminf$ . This motivates the question: what happens if we weaken the condition and require only that  $\int f_n(x) d\mu(x) \leq \varepsilon$  for infinitely many  $\varepsilon$ ? (For the classical version this is not important, since we can delete all the terms of the sequence that are not bounded by  $\varepsilon$ ; this could only increase  $\liminf$  in the conclusion.)

**Acknowledgements.** The authors are thankful to Steve Simpson and Bjorn Kjos-Hanssen for allowing them to include Theorem 12 and Theorem 13, to Peter Cholak for useful discussions, and to two anonymous referees for their numerous comments and suggestions.
